

METHOD FOR SEPARATING MULTICHANNEL SIGNALS PRODUCED BY
AC AND DC SOURCES FROM ONE ANOTHER

FIELD OF THE INVENTION

5

The present invention relates to a novel and advanced method for processing magnetic fields, so-called DC fields, produced by currents independent of time, i.e. DC currents, in multichannel measurements.

10 In particular, the invention relates to a novel manner of eliminating the harmful DC fields caused by the motion of an object being monitored, and on the other hand to a manner of studying interesting DC fields.

In conjunction with this invention, static DC
15 sources, fields and currents independent of time are used to mean both completely static phenomena and those varying at the frequency of one Hertz at the most.

20 BACKGROUND OF THE INVENTION

For measuring biomagnetic signals, magnetometers such as SQUID sensors are usually used, which are sensitive just to dynamic phenomena. In this manner,
25 the DC currents of an object that is immovable with respect to a set of sensors do not cause a measurement signal; and the only way to measure the DC currents is to move the object with respect to the set of sensors. In that case, a static magnetic field distribution
30 produced by the DC currents in the co-ordinates of the object changes in the co-ordinates of the set of sensors as a function of time, thus causing a measurement signal that changes as a function of time.

The DC currents producing DC fields are not
35 usually very interesting, but e.g. in the magnetoencephalographic i.e. MEG measurements there are situations in which it is desirable to perceive DC cur-

rents. Interesting DC currents are associated e.g. with epilepsy, migraine and REM phases of sleep.

In addition to the DC fields caused by physiological DC currents, DC fields are produced by
 5 all the immovable magnetised articles in the coordinates of an object. These can include tiny magnetic particles left in the skull by a drill used in a brain surgery, as well as magnetic impurities e.g. in the hair. As the object moves, magnetisations of this
 10 kind typically produce a very strong interference signal compared to a biomagnetic signal, the elimination and attenuation of which is necessary in order to perceive the physiological phenomenon being studied.

The problem is a typical one specifically in
 15 clinical measurements which measure patients who find it difficult to stay completely immovable during the measurement. In addition to the MEG measurements, the DC fields produced by DC currents can be of importance e.g. in the magnetocardiographic i.e. MKG measure-
 20 ments to be made to study cardiac functions, in which magnetised particles produce a measurement signal e.g. as a result of respiratory movements.

To perceive physiological DC currents, a method has been used in which a testee is moved with
 25 respect to his or her geometry in a manner known se, e.g. periodically at a known frequency and amplitude with respect to the measuring instrument. One such method has been described e.g. in the publications "*Measurement of near-DC biomagnetic fields of the head using a horizontal modulation of the body position*",
 30 Wuebbeler et al, Recent Advances in Biomagnetism, Sendai, pp. 369-372, 1999 and "*Hyperventilation-induced human cerebral magnetic fields non-invasively monitored by multichannel 'direct current' magnetoencephalography*",
 35 Carbon et al, Neuroscience Letters, Vol. 287, pp. 227-230, 2000. In the method in question, the testee is lying on a bed that is movable with respect

to the set of sensors so that the testee's head is supported to be immovable with respect to the bed. This must be done in order that the movement of the head can be assumed to correspond to a known movement
5 of the bed. The bed is moved sinusoidally at the frequency of 0.4 Hz and at the amplitude of 75 mm, whereby the DC currents of the head are visible in the measurement signal at the modulation frequency of 0.4 Hz. The signals are demodulated and reconstructed in a
10 manner enabling one to easily study the DC signals.

The method described above relates to the measurement of interesting physiological DC currents using a magnetoencephalographic apparatus. In the method, the head's own movement is prevented and a
15 movement that is necessary for perceiving DC signals is produced using a means, i.e. a bed. In that case, the magnetisation of the bed also produces a signal of the modulation frequency, which as being an interference signal, must be eliminated e.g. by moving the bed
20 in a corresponding manner without the testee, and by measuring the DC signal due to this so as to be the reference.

Several problems and limitations are associated with the method described above. Especially patients in poor health may experience fastening their
25 head unpleasant. Furthermore, the movement of the bed produces the aforementioned interference signal, the elimination of which, as well as the building of a mechanical movement system and the preparation of DC measurements require a lot of additional work compared
30 to a conventional MEG measurement. Thus, the method is very susceptible to interference.

To eliminate the interference signals produced by "additional" DC fields of a movable testee
35 that are associated with conventional MEG measurements, one has not presented any manner based on the DC property of interference sources. The methods of

interference elimination do not take into account the movement of the testee; instead they just try to eliminate the interference signal caused by movement from the measurements using standard methods. This can
5 be implemented e.g. using high-pass filtering, but the slow brain signals are lost at the same time.

OBJECTIVE OF THE INVENTION

10 The objective of the present invention is to eliminate the disadvantages referred to above or at least to significantly alleviate them. One specific objective of the present invention is to disclose a new type of method which, on the one hand, can be used
15 to examine the interesting physiological DC fields of the testee, and on the other hand, to eliminate the distortions caused by "additional" DC fields in a conventional MEG or MKG measurement. Further, the objective of the present invention is to disclose a solution which ~~can be used~~ to examine interesting DC
20 fields without specific test arrangements and which enables free movement of the testee's head.

As for the features characteristic of the invention, reference is made to them in the claims.

25

DESCRIPTION OF THE INVENTION

 The present invention relates to a novel manner of measuring DC fields using a multichannel MEG or
30 MKG measuring instrument, and on the other hand, to a manner of eliminating from the measurement result the interference signals produced by DC currents. The invention combines the monitoring system of the movement of a testee and the method for motion correction of
35 the measured signals so that the signals produced by the DC currents of a moving testee are visible in the final measurement result as a static signal component

in a conventional MEG or MKG measurement. In that case, in the measurement, there is no need for specifically preparing oneself for the measurement of the DC fields in advance. The aforementioned monitoring system of movement has been described in patent application PCT/FI02/00225 and the method for motion correction in patent application FI20030392. They are incorporated herein by a reference.

The basic idea of the invention is that the movement of a testee's head is monitored, and the movement of the head is modelled as the movement of a set of sensors around an immovable head. The measured magnetic field signal is presented as elementary fields in a signal space basis whose basis vector coefficients have been attached to the co-ordinates of the head utilising the information on the geometry between the head and the measuring instrument. In that case, the behaviour over time of the basis vector coefficients does not involve the distortion caused by the movement of the head; instead the same basis vector coefficients would have also been obtained with a completely immovable head, though with that distinction that in the immovable cases, the coefficients would not have a DC component because SQUID sensors do no measure static phenomena. As the head moves with respect to the measuring instrument, a signal produced by the DC currents appears in the measurement signal, the behaviour over time of which in a non-motion corrected measurement corresponds to the movement of the head. As a result of the aforementioned motion monitoring and motion correction method, the perceived signal produced by a DC current appears in the basis vector coefficients as a static signal because in the co-ordinates of the head, the DC currents produce a static signal.

In calculating the elementary fields, an advantageous embodiment is the use of spherical harmonic

functions, enabling one to easily eliminate the portion of external interference fields at the same time, as presented in patent application FI20030392. The motion correction can also be made in other manners, e.g. utilising the minimum norm estimate of the current distribution of an object being examined.

Thanks to the invention, the processing of signals produced by DC currents is very easy. To examine physiological DC currents, the testee can be requested to freely move his or her head, whereby as a result of motion correction, the DC component of a measurement signal only contains the signal produced in the testee's head by continuous DC currents. A DC component can be separated e.g. by means of a Fourier conversion.

A DC signal obtained by a manner described above naturally is the sum of signals produced by all the DC currents, and contains in addition to the physiological DC signals, also the DC signals of the possible magnetic impurities that can be classified as interference sources, which must be separated from the physiological signals by some method. The elimination of a DC interference from motion corrected data is very easy when the physiological DC signal is not the subject of the examination, because a DC signal can be simply eliminated using a so-called baseline correction. In this correction method, the mean value of a signal is calculated in each measurement channel over a time during which there is no biomagnetic response. In that case, the mean value corresponds to the DC level of the channel, which can be eliminated along the entire measurement period by deducting the numerical value of the DC level in question from the measurement signal.

The invention also enables a novel manner for locating an object being measured with respect to the measuring instrument. As the magnetised articles pro-

duce a signal, corresponding to the movement of the object, it is possible to attach to the object, to known places, in the co-ordinates of the object, magnetic articles, and to measure the movement of the object based on the motion signals of the articles. In that case, the motion monitoring system corresponds to the method described in patent application FI20010558 with the distinction that static signal transmitters are used herein, and the positioning can be performed, if desired, directly from the spatial distribution of the motion signals without the time integration, enabling one to achieve a considerably faster motion monitoring system, a real-time one in practise.

The present invention enables one to examine the physiological, interesting DC fields of a testee on the one hand; and on the other hand, to eliminate the distortions caused in the measurement signal by "additional" DC fields in a conventional MEG or MKG measurement. Thanks to the invention, specific arrangements are unnecessary in these examinations; instead the solution of the invention, when combined with the conventional measurements, gives a possibility to examine DC currents. Further, the invention enables free movement of the testee's head when measuring DC fields.

LIST OF FIGURES

In the following section, the invention will be described in more detail with reference to the accompanying drawings, in which

Fig. 1 schematically represents one measurement arrangement in accordance with the present invention; and

Fig. 2 is a flow chart illustrating one embodiment in accordance with the present invention.

DETAILED DESCRIPTION OF THE INVENTION

Fig. 1 is one advantageous measurement arrangement according to the invention. Fig. 1 illustratively and schematically represents a multi-channel magnetometer 1, which is designated for the measurement of the magnetic fields of the brain. The magnetometer includes a cooled vessel such as a Dewar vessel 2, having inside thereof at a low temperature a set of individual magnetometers i.e. SQUID sensors 3. Arranged in the object being examined 4, herein on the surface of a testee's head, are a set of signal sources 5, whose location in co-ordinates A of the measurement object is known. As the location of the signal sources is known, it is possible, by measuring using the set of sensors 3, to find out the location of the signal sources and also the location of the other signal sources in the measurement object, specifically that of the interesting biomagnetic signal sources.

As the measurement object 4 moves, e.g. as shown by arrows M_1 and M_2 , also the signal sources 5 move, whereby the sensors 3 also register the magnetic fields due to the direct current. Thus, the signal sources can be both direct current and alternating current sources.

In the following section, the functioning of the invention is explained with reference to Figs. 1 and 2. The patent can be requested to move his or her head with respect to the measuring instrument 2, e.g. in the direction of arrows M_1 and M_2 , step 22. The movement can be free, and there is no need to determine it beforehand. The movement is registered using the set of sensors 3, step 23, by utilising the signal sources 5 arranged in the patient's head. The dc sources 6 in the patient's head, which can be associated with interesting biomagnetic phenomena or mag-

netic pieces, produce a direct current component in the magnetic field in the co-ordinates of the head, which is registered by the sensors 3 due to the dynamics caused by the movement of the head. This detected
5 direct current component can be separated from the measurement signal provided that it is presented by means of the elementary field components attached to the co-ordinates of the head taking into account the detected movement, whereby the dc component is visible
10 as a static signal, steps 23, 24 in Fig. 2. The elementary fields can be generated e.g. in the co-ordinates of the head by means of the spherical harmonic functions presented.

The invention is not limited merely to the
15 embodiment examples referred to above; instead many variations are possible within the scope of the inventive idea defined by the claims.
